Supporting Information

ABSTRACT: Formamidinium lead triiodide (HC(NH₂)₂Pbl₃ or FAPbI₃) is gaining increasing interest in the field of mesoscopic perovskite solar cells (PSCs) for its broader light absorption compared with the more widely studied CH₃NH₃PbI₃ (MAPbI₃). Because FAPbI₃ has two polymorphs (“black” α-FAPbI₃ and “yellow” δ-FAPbI₃) at ambient temperature, where α-FAPbI₃ is the desirable photoactive perovskite phase, it becomes particularly important to suppress the formation of the non-perovskite δ-FAPbI₃ for achieving high efficiency in FAPbI₃-based mesoscopic PSCs. In this study, we demonstrate that the judicious use of low-volatility additives in the precursor solution assists in the evolution of α-FAPbI₃ through the formation of non-δ-FAPbI₃ intermediate phases, which then convert to α-FAPbI₃ during thermal annealing. The underlying mechanism involved in the additive-modulated evolution of α-FAPbI₃ upon mesoporous TiO₂ substrates is elucidated, which suggests guidelines for developing protocols for the fabrication efficient FAPbI₃-based mesoscopic PSCs.

1. INTRODUCTION

Organolead halide perovskites with the general formula APbX₃ (A= CH₃NH₃ or HC(NH₂)₂; X = I, Br, or Cl) have recently introduced as light absorber materials in mesoscopic perovskite solar cells (PSCs).1-5 Although methylammonium lead triiodide (CH₃NH₃PbI₃ or MAPbI₃) with a bandgap of ~1.55 eV has been the most widely studied,1,15-17 the perovskite phase (α-FAPbI₃, space group Pmcn)18 cannot be simply generalized to FAPbI₃. FAPbI₃ has two possible polymorphs at ambient temperature:1,5,9,11,17 (i) Trigonal perovskite phase (α-FAPbI₃, space group P3m1), which appears “black” with a direct bandgap of ~1.45 eV. (Note that single-crystal X-ray diffraction has confirmed trigonal crystal structure of α-FAPbI₃,18 but a recent neutron diffraction study of powder samples suggests that α-FAPbI₃ phase may possibly exhibit a simpler cubic perovskite structure.19) (ii) Non-perovskite phase (δ-FAPbI₃, space group P6/mc), which is “yellow” with an indirect bandgap of 2.48 eV. Because the former phase is the desirable photoactive phase with promising optoelectronic properties, suppression of the formation of the latter δ-FAPbI₃ phase is an additional critical requirement for the fabrication of FAPbI₃-based mesoscopic perovskite solar cells (PSCs).17,20 Experimental studies have shown that although the “black” α-FAPbI₃ perovskite phase forms readily on planar substrates via the “one-step” method involving thermal-annealing of a spin-coated stoichiometric FAPbI₃ precursor solution at relatively high temperatures (>140 °C),15,16,21,22 it rarely forms in the same way upon mesoporous TiO₂ scaffolds, regardless of the heat-treatment temperature (see Figure S1 in Supporting Information (SI)). This is presumably associated with the altered crystallization behavior when in contact with high-surface-area mesoporous TiO₂ scaffold.23,24 However, in our early reports, it was revealed that phase-pure α-FAPbI₃ can form upon mesoporous TiO₂ scaffolds from a nonstoichiometric FAI:PbI₂ (FAI:PbI₂ = 1.5:1 molar ratio)7 or FAI-PbCl₂ (FAI:PbCl₂ = 3:1 molar ratio) precursor solutions using the “one-step” method.25 This implies that the use of additives (excess compositions beyond the stoichiometric FAPbI₃ precursors) in the precursor solution enables the formation.
of phase-pure "black" $\alpha$-FAPbI$_3$ perovskite phase upon mesoporous TiO$_2$ scaffolds for mesoscopic PSCs. Herein, we provide insights into the mechanisms involved in the crystallization of the photoactive "black" $\alpha$-FAPbI$_3$ polymorph from solution via comparative use of various additives (NH$_4$Cl, MACl, FACl) with different volatilities in the "one-step" deposition upon mesoporous TiO$_2$ scaffolds. It is demonstrated that the lower-volatility additives that can form intermediate phases from FAPbI$_3$ precursor components suppress the formation of "yellow" $\delta$-FAPbI$_3$ upon precursor-solvent removal at the spin-coating stage. This ultimately enables the gradual evolution of phase-pure $\alpha$-FAPbI$_3$ during the subsequent annealing stage. The overall photovoltaic performance of the as-fabricated FAPbI$_3$-based mesoscopic PSCs shows strong dependence on the purity of the $\alpha$-FAPbI$_3$ perovskite phase.

2. EXPERIMENTAL SECTION

2.1. Materials and Thin-Film Preparation. For the synthesis of CH(NH$_2$)$_2$I (or FAI), 5 g of formamidine acetate (98%, Sinopharm, China) and 10 mL of HI solution (45 wt % in water, Sinopharm, China) were mixed and reacted at 0 °C for 2 h while stirring under N$_2$ atmosphere. However, for the synthesis of CH$_3$NH$_2$Cl (MACl), 5 mL of methylamine (27 wt % in ethanol, Sinopharm, China) and 5 mL of HCl (36 wt % in water, Sinopharm, China) were mixed and reacted at 0 °C for 2 h. Finally, CH(NH$_2$)$_2$Cl (or FACl) was synthesized by mixing and reacting 12 g of formamidine acetate and 10 mL of HCl (36 wt % in water) for 2 h. In each of the above cases, after rotary evaporation, the resulting powders were collected, recrystallized, and washed with a mixture of ethanol and diethyl ether by air-pump filtration. The solids were finally dried at 60 °C under vacuum.

A TiO$_2$ sol was prepared by mixing 10 mL of titanium(IV) isopropoxide (99%, Aldrich-Sigma, U.S.A.) with 50 mL of 2-methoxyethanol (98%) and 5 mL of ethanolamine (99%, Sinopharm, China) in a three-necked flask, each connected with a condenser, thermometer, and argon gas inlet/outlet. The mixed solution was heated to 80 °C for 2 h while under magnetic stirring, followed by heating to 120 °C for 1 h. This two-step heating was then repeated two times to result in a viscous solution.

Powder of $\delta$-FAPbI$_3$ and $\alpha$-FAPbI$_3$ were synthesized as follows. PbI$_2$ (99%, Aldrich-Sigma, U.S.A.) and FAI in molar ratio 1:1 were dissolved in dimethylformamide (DMF, Aldrich-Sigma, U.S.A.) solution (40 wt %), and then drop-cast on glass slides and heated at 60 °C in air to produce "yellow" $\delta$-FAPbI$_3$ crystals. These crystals are scratched from the glass slides and collected. For the synthesis of $\alpha$-FAPbI$_3$ powders, the same procedure was followed except for the use of 140 °C annealing temperature and N$_2$ atmosphere.

2.2. Material and Film Characterization. X-ray diffraction (XRD) patterns were obtained on a diffractometer (D8 Advance, Bruker, Germany) using Cu K$_\alpha$ radiation, with 0.02° step. UV−vis absorption spectra of the perovskite films were recorded using a spectrometer (U-4100, Hitachi, Japan). A field-emission SEM (S-4800, Hitachi, Japan) was used to observe the top surfaces and cross sections. All films for XRD, SEM, and UV−vis were deposited on FTO/glass substrates with a 30 nm layer of dense TiO$_2$ and a 300 nm layer of mesoporous TiO$_2$. The precursor solutions with or without
additives were spin-coated on these substrates at 4000 rpm for 40 s. Differential scanning calorimetry (DSC) measurements (PerkinElmer, Waltham, MA) were performed at a heating rate of 10 °C/min under N2 atmosphere.

2.3. Solar Cells Fabrication and Testing. Fluorine-doped tin oxide (FTO) coated glass was patterned by etching with Zn powder and 1 M HCl diluted in distilled water. The etched substrate was then cleaned with ethanol, saturated KOH solution in isopropanol, and water, and then dried with clean dry air. Subsequently, 30 nm thick dense TiO2 layer was deposited on the FTO glass by spin-coating (4000 rpm, 45 s) the TiO2 sol from above, followed by a heat-treatment at 500 °C for 30 min in air. Subsequently, 300 nm thick TiO2 mesoporous layer was deposited on the TiO2 dense layer by spin-coating (4000 rpm, 30 s) a diluted commercial TiO2 paste, followed by a sintering heat-treatment of 550 °C for 30 min in air.

The FAPbI3 films were then deposited using the conventional “one-step” method. Here, a 35 wt % PbI2:FAI (molar ratio of 1:1) solution in DMF was spin-coated (4000 rpm, 45 s), followed by a heat-treatment at 140 °C. In case of additives, NH4Cl or MACl or FACl with equal molar amount were added to the precursor solution. A solution of spiro-MeOTAD hole-transporting material (HTM) was prepared by dissolving 72.3 mg of spiro-MeOTAD in 1 mL of chlorobenzene (99.8%, Aldrich-Sigma, U.S.A.), to which 28.8 μL of tert-butylpyridine (96%, Aldrich-Sigma, U.S.A.) and 17.5 μL of lithium bis(trifluoromethanesulfonyl)imide (LITSFI, Aldrich-Sigma, U.S.A.) solution (520 mg LITSFI (98%) in 1 mL acetonitrile (99.8%, Aldrich-Sigma, U.S.A.) were added. The HTM layer was then vacuum evaporated to complete the PSCs fabrication.

Current density (J)—voltage (V) characteristics of the as-fabricated PSCs were measured using a 2400 Sourcemeter (Keithley, U.S.A.) under simulated one-sun AM 1.5G 100 mW cm−2 intensity (Oriel SolS Class AAA, Newport, U.S.A.), under both reverse (from VOC to JSC) and forward (from JSC to VOC) scans. The step voltage was 50 mV with a 10 ms delay time per step. The maximum-power output stability of the PSCs was measured by monitoring the PCE output at the maximum-power point (Oriel Sc 1500A) scans. The step voltage was 50 mV with a 10 ms delay time per step. The maximum-power output stability of the PSCs was measured by monitoring the J output at the maximum-power V bias (deduced from the reverse-scan J–V curves). The J output is converted to PCE output using the following relation: 

\[ \text{PCE} = \frac{J \times V}{(100 \text{ mW cm}^{-2})} \]

A shutter was used to switch on and off the one-sun illumination on the PSC. Typical, active area of the PSCs is 0.09 cm2 defined using a nonreflective metal mask.

3. RESULTS AND DISCUSSION

Figure 1A is a schematic diagram showing the FAPbI3 phase formation upon mesoporous TiO2 scaffolds by thermal annealing (140 °C) of spin-coated stoichiometric precursor films with and without the various additives (NH4Cl, MACl, FACl). As shown in the Figure 1 and the UV–vis absorption spectra of the films (Figure S2 in SI), without additive and with NH4Cl additive, annealing the precursor solution results in the formation of significant amount of “yellow” δ-FAPbI3 phase (Reaction 1). When MACl and FACl additives are used, high-purity “black” α-FAPbI3 phase evolves (Reaction 2)

\[ \text{PbI}_2(l) + \text{FAI}(l) \rightarrow \delta-\text{FAPbI}_3(s) \]  
\[ \text{PbI}_2(l) + \text{FAI}(l) \rightarrow \alpha-\text{FAPbI}_3(s) \]  
\[ \delta-\text{FAPbI}_3(s) \rightarrow \alpha-\text{FAPbI}_3(s) \]

In order to understand the above phase evolution behavior, X-ray diffraction (XRD) and energy dispersive spectroscopy (EDS) studies were conducted. Figure 1B–E show XRD patterns from freshly spin-coated films, and thermally annealed (140 °C) films (5 and 30 min) for each additive case, and Figure 1F shows the change of the Cl content in the films with increasing annealing duration. Four sets of samples are measured: (Figure 1B) stoichiometric FAPbI3 precursor solution without additive; (Figure 1C) with NH4Cl additive; (Figure 1D) MACl additive; and (Figure 1E) with FACl additive. Note that the molar ratio of the additive to FAI or PbI2 precursor is 1:1. See complete indexing of the XRD peaks of the α-FAPbI3 powders (A) before and (B) after thermal annealing (140 °C for 30 min); XRD patterns from “yellow” δ-FAPbI3 thin films upon mesoporous TiO2 scaffolds (C) before and (D) after thermal annealing (140 °C for 30 min). The molar amount of the additive is equal to that of FAI or PbI2.

Figure 2. XRD patterns from “yellow” δ-FAPbI3, powders (A) before and (B) after thermal annealing (140 °C for 30 min); XRD patterns from “yellow” δ-FAPbI3 thin films upon mesoporous TiO2 scaffolds (C) before and (D) after thermal annealing (140 °C for 30 min). The molar amount of the additive is equal to that of FAI or PbI2.
In the case of MACl additive, right after the spin-coating step a “black” film is visible to the naked eye, instead of a “yellow” film as in the no-additive and NH4Cl additive cases. The corresponding XRD patterns (Figure 1D) are strikingly different as well. In Figure 1D, the XRD pattern for the freshly spin-coated sample shows a strong, well-resolved peak. At first glance, there appears to be no obvious difference in that peak as compared with the annealed films (5 and 30 min). However, a closer look at the peak positions ([Figures S5 in SI]) shows that there is a measurable shift to lower 20. The peaks at 14.02° and 28.18° in the XRD pattern for the freshly spin-coated sample are shifted to 13.90° and 28.06°, respectively, in the final film (30 min). To investigate this interesting change in the XRD patterns before and after annealing, UV–vis absorption spectra from both the films were collected. The absorption edge shift from 780 nm for the freshly spin-coated film to 830 nm for the 30 min-annealed film observed in Figure S6 in SI matches the absorption features of MAPbI3,27,28 and α-FAPbI3 perovskites.29,30 Thus, it is reasonable to deduce that the perovskite that forms initially during the spin-coating of the film is MAPbI3, gradually converts to α-FAPbI3 in the final film, as proposed in Reaction 4. First, an anion-exchange reaction between FAI precursor and MACl additive is likely to occur, which results in the formation of the MAPbI3 (solid) and FACl right after spin-coating. To demonstrate the feasibility of such anion-change reaction, a solution of PbI2:FACl:MAI = 1:1:1 (molar ratio) in DMF was spin-coated, where the film evolution was observed to be identical. With the formation of the intermediate mixture of MAPbI3 and FACl, the subsequent thermal annealing produces α-FAPbI3 and MACl via cation-exchange reaction between MAPbI3 and FACl. Because α-FAPbI3 is thermally more stable than MAPbI3, the MACl additive tends to sublime during high-temperature annealing step. In that case, Reaction 4 moves forward, resulting in the formation of a phase-pure α-FAPbI3 film. The chlorine amount is also monitored using EDS. The results in Figure 1F show a large initial amount of Cl (Cl/Pb = 1 atomic ratio) in the spin-coated films, but after 5 min annealing the Cl amount is reduced (Cl/Pb = 0.1 atomic ratio), and finally no EDS-detectable Cl is found in the final film (30 min annealing). This further supports the Cl-modulated chemical process given in Reaction 4

$$\text{FAI}(l) + \text{PbI}_2(l) + \text{MACl}(l) \rightarrow \text{MAPbI}_3(s) + \text{FACl}(s)$$ \hspace{1cm} \rightarrow \alpha-\text{FAPbI}_3(s) + \text{MACl}(g) \hspace{1cm} (4)$$

$$\text{FAI}(l) + \text{PbI}_2(l) + \text{FACl}(l) \rightarrow \text{FAI-PbI}_2\text{-FACl}(s)$$ \hspace{1cm} \rightarrow \alpha-\text{FAPbI}_3(s) + \text{FACl}(g) \hspace{1cm} (5)$$

In the case of FACl additive, XRD pattern (Figure 1E) from the freshly spin-coated film does not show the presence of δ-FAPbI3 either, but rather an unknown intermediate phase appears to be present. The intermediate phase is likely to be FAI-PbI2-FACl adduct formed by interaction of Lewis base halide (I– or Cl–) and the Lewis acid PbI2.29 In order to confirm the FAI-PbI2-FACl adduct formation, Figure S7 in SI shows Fourier-transform infrared (FTIR) spectra of solid samples prepared by spin-coating using DMF solutions of FAI, FAI:PbI2 (= 1:1), FAI:PbI2:FACl (= 1:1:1), FACl:PbI2 (= 1:1), and FACl, in which the stretching vibration of C=N (υ(C≡N)) appears at 1697.6 cm⁻¹, 1709.6 cm⁻¹, 1711.1 cm⁻¹, 1713.0 cm⁻¹, and 1720.3 cm⁻¹, respectively. The υ(C≡N) (1697.6 cm⁻¹) in FAI shows lower wavenumber than that (1720.3 cm⁻¹) in FACl, which is due to the stronger electron affinity of chlorine compared to iodine. With presence of Lewis acid PbI2, the υ(C≡N) are both lowered to 1709.6 and 1713.0 cm⁻¹ in the cases of FAI and FACl, which is related to the coordination of Lewis base halide (I– or Cl–) with PbI2. In the case of FAI:PbI2:FACl (= 1:1:1), the υ(C≡N) shows a medium value of 1711.1 cm⁻¹, which suggests the formation of the FAI-PbI2-FACl adduct with mixed coordination behavior of the halide (I– and Cl–) with PbI2. With subsequent annealing, there is a gradual reduction of the intermediate mixture, accompanied by the formation of crystalline “black” α-FAPbI3 perovskite phase. The EDS results (Figure 1F) show that the rate at which the Cl content in the films decreases is relatively small compared to that in the MACl case. Still, considerable Cl amount (Cl/Pb = 0.6 atomic ratio) remains in the 5 min annealed film compared with Cl/Pb = 0.1 in the MACl case. After 30 min of annealing, the Cl has completely sublimed/evaporated. The increase in the amount of the α-FAPbI3 phase and the corresponding decrease of the Cl content suggests that sublimation of Cl is one of the major driving forces for Reaction 5, which is similar to the MACl case (Reaction 4). The XRD and EDS results are also consistent with the evolution of the optical-absorption feature of phase-pure α-FAPbI3 with annealing duration, as shown in Figure S8 in SI.

In order to support the phase-evolution argument discussed above, studies were conducted on free-standing powders. Figure 2A–B show the conversion of the “yellow” δ-FAPbI3 phase to the “black” α-FAPbI3 phase after annealing at 140 °C for 30 min. Also, DSC measurements shows that the “yellow” δ-FAPbI3 powder starts to absorb heat at ~140 °C, whereas the “black” α-FAPbI3 powder does not (Figure S9 in SI), confirming the occurrence of a phase transformation. Note that although the heat-treatments experiments are conducted isothermally, the DSC heating rate is 10 °C/min, which could be responsible for the heat-absorption peak occurring at a higher temperature of ~155 °C. This is consistent with the DSC results reported by Seok et al.31 In contrast, this beneficial phase transformation is suppressed in FAPbI3 thin films upon mesoporous TiO2 scaffolds, as shown in Figure 2C–D. Because the area of the interface between FAPbI3 and the substrate has increased significantly with introduction of the mesoporous TiO2 scaffold, it is possible that the attendant increase in the relative interfacial energy may suppress the δ-to-α phase transformation in FAPbI3. Although the exact reason behind this distinct phase transformation behavior with or without the mesoporous TiO2 scaffold is the subject of follow-up studies, the results presented here highlight the importance of suppressing δ-FAPbI3 formation during all reaction stages in the deposition of FAPbI3 upon mesoporous TiO2 scaffolds.

On the basis of the experimental observations above, the underlying mechanisms of the evolution of the “black” α-FAPbI3 phase are shown schematically in Figure 3. We emphasize here that the “one-step” deposition method entails spin-coating of precursor solution followed by thermal annealing, where the DMF solvent, which is volatile despite its high boiling point, is typically used.1 Therefore, the high-speed spin-coating of precursor solutions on the substrate is coupled with rapid evaporation of precursor solvent, which induces supersaturation, resulting in the precipitation of solids.30 Note that the FTIR spectrum in Figure S10 in SI does not show obvious presence of DMF in the freshly spin-coated films, which suggests that most of the solvent-state DMF
molecules have evaporated during spin-coating. Because the supersaturation driven by centrifugal force occurs upon a mesoporous TiO2 scaffold at room temperature, substantial amount of the “yellow” δ-FAPbI3 phase is formed via Reaction 2 immediately after spin-coating in the absence of any additives (Figure 1B). In the case of NH4Cl additive, due to its high volatility, only a very small amount of the additive remains in the film and the formation of the “yellow” δ-FAPbI3 phase at this stage is inevitable. Furthermore, the conversion of the “yellow” δ-FAPbI3 phase to the “black” α-FAPbI3 phase upon mesoporous TiO2 scaffolds via Reaction 3 does not occur in the subsequent annealing stage, and thus, the as-formed δ-FAPbI3 remains in the resultant solid films. The formation of minor amount of α-FAPbI3 is associated with a small amount of low-crystallinity intermediate phases. However, in the presence of MACl or FACl, the formation of the respective intermediate phases is favored over δ-FAPbI3 during the initial spin-coating stage. In this situation, during the subsequent high-temperature annealing, the “black” α-FAPbI3, which is the thermodynamically stable perovskite phase, gradually evolves along with the sublimation of Cl species.

Figure 4 shows surface morphology of as-prepared FAPbI3 (δ-FAPbI3 or α-FAPbI3) layer on mesoporous TiO2 substrates, without and with additives (NH4Cl, MACl, FACl). Because the surface morphology of the FAPbI3 solids is primarily affected by the reaction kinetics of its formation, the additives can exert great influence on the final morphology of these layers. And the nucleation and the growth stages in the formation of organic–inorganic hybrid materials can occur simultaneously, which is responsible for the poor coverage in the one-step processed thin films.31,32 In this context, the poor morphology of the as-formed FAPbI3 in Figure 4A is typical. As discussed above, although NH4Cl is used as an additive in the precursor solution, it evaporates or sublimes rapidly during spin-coating. Consequently, the morphology of the resulting FAPbI3 thin film is not improved (Figure 4B). However, in the case of MACl (Figure 4C) or FACl (Figure 4D), the overall coverage of FAPbI3 on the mesoporous TiO2 is improved significantly. This is attributed to the slowing of the reaction kinetics due to the presence of the additives in the film. This is further supported by results from the study of the effect of the additive amount on the final morphology of the α-FAPbI3 thin films. Similar to what is reported by Zhao et al.33 in the case of MAPbI3, the overall precursor-to-perovskite conversion rate is reduced with an increase in the additive amount, which produces films with different morphologies (Figure S11 in SI). With optimization, the use of equal-molar FACl:FAI or FACl:PbI2 results in the near-complete coverage in the final
perovskite film. These observed morphology changes due to the use of different additives, or the use of different amount of the same additive, are consistent with the proposed Cl-modulated reaction routes in each situation.

Mesoscopic PSCs were fabricated to correlate the photovoltaic performance with the perovskite phase purity and the film coverage. The cross section of a typical mesoscopic PSC is shown in Figure 5A, where the mesoporous TiO₂/FAPbI₃ layer, along with a thin capping FAPbI₃ layer, are sandwiched between a compact TiO₂/FTO electron-extraction layer and a spiro-OMeTAD/Ag hole-extraction layer. The J−V curves for the PSCs made without and with additives are shown in Figure 5B, and the efficiency statistics are shown in Figure S12 in SI. The importance of phase purity on the overall solar cell performance is readily reflected in the J−V curves. Because the major component in the no-additive and NH₄Cl additive cases is the undesirable nonperovskite “yellow” δ-FAPbI₃ phase, the overall power conversion efficiencies (PCEs) of these PSCs is 0.2−0.7%. In the case of MACl and FACl additives, the PCEs are significantly enhanced, further attesting the formation of phase-pure α-FAPbI₃ perovskite upon mesoporous TiO₂ scaffolds. Because the coverage of α-FAPbI₃ is another factor that influences the performance of FAPbI₃-based mesoscopic PSCs, the best PSC with PCE of 13.7% is made from the use of equimolar FACl additive that results in near-full coverage. In contrast, in the case of MACl additive, the presence of more pinholes in the α-FAPbI₃ film are responsible for the relatively lower PCE of 7.0% of those PSCs. Because typical hysteresis is present in these PSCs (Figure S13 in SI), the stabilizing power output at maximum power point is monitored, showing a stable 12.7% at ~200 s duration (Figure S14 in SI). The effect of FACl additive amount on the J−V characteristics of the resultant mesoscopic PSCs are also studied, and the results are presented in Figure S15 in SI, which confirms that overall performance is enhanced by optimal coverage of the thin perovskite capping layer (Figure S11 in SI). These results highlight the importance of the evolution of full-cover photoactive “black” α-FAPbI₃ in achieving high efficiency in FAPbI₃-based mesoscopic PSCs.

**CONCLUSIONS**

We have demonstrated that suppressing the formation of the nonperovskite “yellow” δ-FAPbI₃ phase at all stages of the formation of FAPbI₃ on mesoporous TiO₂ scaffolds is essential for achieving high-purity “black” α-FAPbI₃ perovskite phase. This is because it is very difficult to convert an as-formed δ-FAPbI₃ phase to α-FAPbI₃ perovskite phase during subsequent thermal-annealing due to a barrier to the δ-to-α phase transformation associated with the presence of the mesoporous TiO₂ scaffold. Low-volatility additives such as FACl and MACl are good candidates for assisting in the crystallization of phase-pure α-FAPbI₃ via the formation of intermediate mixtures, which prohibits the crystallization of the δ-FAPbI₃ phase. It is worth noting that additives, which are commonly regarded as agents for improving the film uniformity in the case of “one-step” solution-deposition of MAPbI₃, are of more importance in the case of FAPbI₃, especially in the context of the phase evolution of the desirable perovskite phase upon mesoporous TiO₂ scaffolds. This study provides an understanding of the crystallization behavior of FAPbI₃ from precursors with and without additives and suggests guidelines for the development of effective processing protocols of FAPbI₃ and other polymeric materials (e.g., CsSnI₃, CsPbI₃) for mesoscopic photovoltaics.
